Abstract

In this paper, we consider a three node, two-way relay system with digital network coding. The aim is to minimize total energy consumption while ensuring queue stability at all nodes, for a given pair of random packet arrival rates. Specifically, we allow for a set of transmission modes and solve for the optimal fraction of resources allocated to each mode. First we formulate and solve the static-channel problem, where all link gains are constant over the duration of transmission. Then we solve the fading-channel problem, where link gains are random. We call the latter the ergodic energy efficiency problem, and show that its solution has a water-filling structure. Finally, we provide a detailed analysis of the queues at each node using a random scheduling method that closely approximates the theoretical design, through a two-dimensional Markov chain model.

Two-way relays, network coding, energy efficiency, queue stability

I. INTRODUCTION

Network coding [3] has emerged as a viable means to improve throughput in complex networks. Messages at the packet level are linearly combined at intermediate nodes and forwarded to multiple intended destinations. Using knowledge of the manner in which messages were combined, communicated through some additional overhead bits, as well as knowledge of the message it contributed, a destination can successfully reconstruct the message intended for it. In this way, network throughput is greatly improved.

The two-way relay network [4] exemplifies the use of network coding in digital communication. This simple network comprises two source nodes (S_1 and S_2) and one relay node (R), where S_1 and S_2 have information to exchange with each other. A direct link between S_1 and S_2 is unavailable. This model applies for instance to communication between a base station and a mobile user in cellular communications, in which the mobile user is in a location shadowed from the base station and coverage is provided in the area by means of a relay. Another typical application is that of satellite communication, where two satellites have messages for each other and can only communicate through a ground station.

Parts of this work were presented at IEEE ICC (International Conf. on Communications in China) 2012, and submitted to IEEE ICCS (International Conf. on Communication Systems) 2012. With the aid of network coding, we can exchange two messages in two time slots with physical network coding [6], [10], [11] or three slots with digital network coding [4], [5], compared with the four slots needed with pure forwarding. With network coding, the relay receives messages from both source nodes, then combines these messages and broadcasts the network-coded packet to S_1 and S_2 . The rate region for DNC-based two-way relay networks was first explored in [4], [5] with various transmission modes including one-way forwarding and network-coded broadcasting. The former also investigated queue stability in the case of random data arrivals at each source node. The seminal work on physical layer network coding (PNC) presented in [6] showed that two slots is sufficient for two packet transmissions provided that receiver-side SNR is sufficiently high and perfect synchronization could be achieved. [7] and [8] discussed the practical design of asynchronous PNC systems. Multiuser detection was applied at the relay node to exploit asynchronous transmission in the uplink to form a network coded packet in the downlink.

In addition to throughput, resource allocation was investigated in [9], [12], [13], [15]. In [9], optimal resource allocation with data fairness was discussed. Optimal resource allocation for analog network coding in a MIMO two-way relay network was investigated in [10]. In [12] and [13], optimal resource allocation for an ANC-based system was considered for OFDM systems. In [15], resource allocation was investigated under the scenario of asymmetric multi-way relay communication over orthogonal channels.

In [14], the fading nature of a wireless channel was taken into consideration and the optimal position for the relay node was investigated. In [16], outage regions of DNC and ANC strategies were derived. It found that with the presence of a direct link, DNC was more promising than ANC in most cases in terms of outage performance.

In this paper, we formulate, simplify and solve the problem of allocation of channel resources to the various transmission modes in a DNC-based two-way relay network to minimize total energy usage in transmission. The constraint in the optimization problem is that queue stability is maintained at all four queues in the network for a given pair of average packet arrival rates λ_1 and λ_2 at S_1 and S_2 , respectively. The scheduler, e.g., the relay node, is assumed to have full knowledge of the instantaneous channel coefficients in the four flat-fading links.

There are two scenarios to consider in such an energy minimization problem: (i) static channels, which remain unchanged over the entire duration of the transmission; and (ii) fading channels, which change

with time so that over the duration of the transmission, all channel states are visited. For static channels, queue stability requires that throughput from S_1 (S_2) is at least λ_1 (λ_2) for a given set of channel gains; for fading channels, queue stability is guaranteed as long as throughput from S_1 averaged over the fading distribution is at least λ_1 . In the fading case, the resulting optimization problem is solved by a water-filling procedure over the state space of the fading gains. This is tied to the solution of the static channel problem, which we will show to be equivalent to a convex optimization problem and hence is easily solved.

Assuming ergodicity in the channel processes, the fading-channel solution minimizes the long-term average energy used to deliver the arrival rate pair (λ_1, λ_2) . The derivation of this result is a natural complement to the first static-channel energy optimization problem.

Subsequently, we also design and simulate a random scheduling protocol based on the two designed resource allocation policies. To maintain finite queue length at each node, we introduce a back-off parameter ϵ , so that the designed arrival rate is $\lambda_i(1 + \epsilon)$ for an actual arrival rate of λ_i . This leads to the total energy usage being smaller than the objective function used in our design optimization. We investigate the behavior of the queues at the source nodes and the relay, for the random scheduling algorithm. Finding the average delay and queue length at S_1 and S_2 is straightforward, however the analysis of the two queues at the relay (for data from S_1 and S_2 respectively) required the use of a two-dimensional Markov chain. We present and verify through simulations this analysis in the second part of this paper.

The rest of this paper is organized as follows. In Section II, we introduce the energy usage optimization problem over static channels and provide the solution to this problem. In Section III, we introduce the ergodic energy usage optimization problem and present the associated solution with the water-filling structure. In Section IV, we present an energy efficient random scheduling protocol and provide the queueing analysis for this protocol. Simulation results are presented in Section V and Section VI concludes this work.

Notation: Scalars are denoted by lower-case letters and bold-face lower-case letters are used for vectors and bold-face upper-case letters for matrices. In addition, we use $\mathbf{I}$ and $\mathbf{\Theta}$ to denote the identity matrix and the all-unity matrix respectively. $\mathbf{1}$ is the row vector with all elements equal to unity.

Fig. 1. System model for a two-way relay network with random packet arrivals.

II. STATIC CHANNEL PROBLEM

In this section, we discuss the static channel problem, where the channel gains g_{1r} , etc. depicted in Figure 1 are deterministic, modelling the block-fading case, or simply the case of fixed channels as seen in wired systems.

A. System Model and Problem Formulation

Figure 1 depicts the two-way relay network of interest. Assume that packets arrive at S_i according to a Poisson process at an average arrival rate of λ_i , $i \in \{1, 2\}$, and we seek to maximize the energy efficiency of this system for a given average arrival rate pair (λ_1, λ_2) while maintaining queue stability, by adjusting the fraction of time allocated to each of the following five transmission modes:

- *Mode 1*: S_1 transmits to R at rate R_1 (uplink phase).
- *Mode 2*: S_2 transmits to R at rate R_2 (uplink phase).
- *Mode 3*: R broadcasts to S_1 and S_2 at broadcast rate R_3 (Network coding in downlink phase).
- *Mode 4*: R transmits only to S_1 at rate R_4 (one-way forwarding in downlink phase).
- *Mode 5*: R transmits only to S_2 at rate R_5 (one-way forwarding in downlink phase).

The four channel (power) gains g_{1r} , g_{2r} , g_{r1} and g_{r2} , correspond to modes 1, 2, 4 and 5 respectively¹. For convenience, we define $g_1 = g_{1r}$, $g_2 = g_{2r}$, $g_3 = \min(g_{r1}, g_{r2})$, $g_4 = g_{r1}$ and $g_5 = g_{r2}$ so that g_i is the channel gain in Mode i . Receiver noise for each mode is modeled by i.i.d. Gaussian random variables with zero mean and unit variance. The power transmitted in Mode i is denoted P_i . In other words, the signal to noise ratio (SNR) at the receiver in Mode i is

$$\text{SNR}_i = P_i g_i. \quad (1)$$

To achieve a rate of R_i in Mode i therefore requires that P_i be exponentially related² to R_i , via

$$P_i(R_i) = \frac{2^{R_i} - 1}{g_i}, \quad i = 1, \dots, 5. \quad (2)$$

¹Note that whether $g_{ri} = g_{ir}$ is inconsequential in this work.

²An SNR gap term Γ can be inserted into the expression but this only changes the effective channel gain to g_i/Γ and does not affect the following discourse.

It should be noted that in Mode 3, the rate of R_3 is the rate transmitted to *each* of S_1 and S_2 , due to the use of network coding.

Suppose that a fraction f_i , $i = 1, \dots, 5$, of each time slot is allocated to Mode i respectively. Therefore $f_i P_i(R_i)$ is proportional to the energy used for transmission in Mode i , if we disregard the possibility that queues may be empty. To minimize the total energy consumption per time slot while satisfying queue stability constraints therefore requires the solution of optimization problem **P1**:

$$\min_{f_i, R_i} \sum_{i=1}^5 f_i P_i(R_i) \quad (3)$$

subject to the queue stability constraints

$$\lambda_1 \leq \min(f_1 R_1, f_3 R_3 + f_5 R_5) \quad (4)$$

$$\lambda_2 \leq \min(f_2 R_2, f_3 R_3 + f_4 R_4) \quad (5)$$

and the physical constraints $\sum_{i=1}^5 f_i \leq 1$ and $f_i \geq 0$. In the next section, we show that **P1** can be transformed into a simpler convex optimization problem with only f_i as the design parameters and hence can be solved easily.

Finally, the queue lengths (in terms of packets) at S_1 and S_2 at epoch t are denoted by $Q_1(t)$ and $Q_2(t)$. We also define $Q_{r1}(t)$ and $Q_{r2}(t)$ as the lengths of the two queues maintained at the relay node for S_1 and S_2 , respectively.

B. Problem Solution

Problem **P1** may be simplified through the following lemmas.

Lemma 1: Under the optimal solution to **P1**, we have

$$\begin{cases} f_4 = 0, & \text{if } \lambda_1 > \lambda_2 \\ f_5 = 0, & \text{if } \lambda_1 < \lambda_2 \end{cases} \quad (6)$$

and $f_4 = f_5 = 0$ if $\lambda_1 = \lambda_2$.

Proof: Denote the optimal values of f_i and R_i by f_i^* and R_i^* . Constraints (4) and (5) dictate that

$$f_3^* R_3^* + f_5^* R_5^* \geq \lambda_1 \quad (7)$$

$$f_3^* R_3^* + f_4^* R_4^* \geq \lambda_2 \quad (8)$$

Assume that $f_3^* R_3^* + f_4^* R_4^* - \lambda_2 = \epsilon > 0$. Then reducing f_4^* by ϵ/R_4 while keeping all other f_i^* and all R_i^* fixed results in constraint (5) still being satisfied, with a lower total energy. Therefore we can assume that $f_3^* R_3^* + f_4^* R_4^* = \lambda_2$. Similarly, $f_3^* R_3^* + f_5^* R_5^* = \lambda_1$.

Suppose that $f_4^* > 0$. If we reduce f_4^* by δ_4 , constraint (5) requires that f_3^* be increased by $\delta_4 R_4^*/R_3^*$. This in turn means that f_5^* can be reduced by $\delta_4 R_4^*/R_5^*$. In other words, queue stability is maintained under the following adjustment:

$$\begin{aligned} f_4^* &\rightarrow f_4^* - \delta_4 \\ f_3^* &\rightarrow f_3^* + \delta_4 R_4^*/R_3^* \\ f_5^* &\rightarrow f_5^* - \delta_4 R_4^*/R_5^* \end{aligned}$$

The total energy used is now reduced by

$$\Delta E = \delta_4 \left(\frac{R_4^*}{R_5^*} P_5^* + P_4^* - \frac{R_4^*}{R_3^*} P_3^* \right) \quad (9)$$

where P_i^* is shorthand for $P_i(R_i^*)$. Note that R_3^* , R_4^* and R_5^* need only satisfy two equations equivalent to

$$\begin{aligned} f_5^* R_5^* - f_4^* R_4^* &= \lambda_1 - \lambda_2 \\ f_3^* R_3^* + f_5^* R_5^* &= \lambda_1. \end{aligned} \quad (10)$$

We can thus always find a point in the solution space of (10) to make the term in brackets in (9) positive. So as long as $\delta_4 > 0$ does not lead to a violation of (10), we can reduce total energy by $\Delta E > 0$. If $\lambda_1 > \lambda_2$, this result and (10) show that we should have $f_4^* = 0$, and $f_5^* R_5^* = \lambda_1 - \lambda_2$.

Similarly, if $\lambda_1 < \lambda_2$, then $f_5^* = 0$ and $f_4^* R_4^* = \lambda_2 - \lambda_1$; and if $\lambda_1 = \lambda_2$, then $f_4^* = f_5^* = 0$. ■

A corollary of Lemma 1 is that, since either one or both of f_4^* and f_5^* must be 0, f_3^* cannot be zero, i.e. the broadcast phase (Mode 3) must be used. This is intuitive because one bit transmitted in Mode 3 is equivalent to two bits delivered, and hence we should devote as much resources as possible to Mode 3. The following lemma links R_i to f_i .

Lemma 2: The solution to **P1** satisfies

$$R_i^* = \frac{\lambda_i}{f_i^*}, \quad i = 1, 2 \quad (11)$$

$$R_3^* = \frac{\min(\lambda_1, \lambda_2)}{f_3^*} \quad (12)$$

$$R_4^* = \max \left(\frac{\lambda_2 - \lambda_1}{f_4^*}, 0 \right) \quad (13)$$

$$R_5^* = \max \left(\frac{\lambda_1 - \lambda_2}{f_5^*}, 0 \right) \quad (14)$$

Proof: By reducing f_1 and/or R_1 , total energy is reduced, and so the energy-minimization problem must be solved when $f_1 R_1$ is at its smallest value, i.e. $f_1^* R_1^* = \lambda_1$. Similarly, $f_2^* R_2^* = \lambda_2$.

Equations (13) and (14) arise directly from the proof of Lemma 1. Equation (12) comes from noting that if $\lambda_1 < \lambda_2$, Lemma 1 states that $f_5^* = 0$ and hence $f_3^* R_3^* = \lambda_1$ while if $\lambda_1 > \lambda_2$, $f_3^* R_3^* = \lambda_2$. ■

Lemma 2 implies that $\{R_i\}$ can be removed as optimization variables, leaving only $\{f_i\}$ in an equivalent optimization problem. Lemma 1 (and also Lemma 2) implies that when $\lambda_1 > \lambda_2$, Mode 4 (forwarding from the relay to S_1) is not necessary, and that when $\lambda_1 < \lambda_2$, Mode 5 is not necessary. Hence there is no loss of generality in assuming that $\lambda_1 < \lambda_2$ from this point on, so that Mode 5 is no longer discussed and the min and max functions need not be invoked in Lemma 2. We now have

$$R_3^* = \frac{\lambda_1}{f_3^*}, \quad R_4^* = \frac{\lambda_2 - \lambda_1}{f_4^*} \text{ and } R_5^* = 0. \quad (15)$$

By substituting the new expressions for $\{R_i\}$ into **P1**, assuming $\lambda_1 < \lambda_2$, we get the equivalent optimization problem **P2**:

$$\begin{aligned} \min_{f_i} \quad & f_1 P_1 \left(\frac{\lambda_1}{f_1} \right) + f_2 P_2 \left(\frac{\lambda_2}{f_2} \right) + f_3 P_3 \left(\frac{\lambda_1}{f_3} \right) \\ & + f_4 P_4 \left(\frac{\lambda_2 - \lambda_1}{f_4} \right) \end{aligned} \quad (16)$$

$$\text{s.t.} \quad f_i \geq 0 \quad (17)$$

$$\sum_{i=1}^4 f_i \leq 1 \quad (18)$$

where the power functions $P_i(\cdot)$ are given by (2).

It is not difficult to show that the cost function in **P2** is convex in $\{f_i\}$, and clearly the constraint set is also convex. Therefore the original problem **P1** has been turned into an equivalent convex optimization problem **P2**.

It should be noted too that the cost function in **P2** is monotonically decreasing in $\{f_i\}$ and hence its solution must lie on the boundary of the constraint set. Since $f_i = 0$ for all i is clearly not a viable solution, it must be that $\sum_i f_i = 1$ i.e., that all available time resources are fully utilized. This is easily understandable since increasing any f_i leads to a corresponding reduction in the associated R_i , which means an exponential decrease in required power and hence we would want f_i to be as large as possible.

Since **P2** is a constrained convex optimization problem, its solution is found by solving the the Karush-Kuhn-Tucker (KKT) equations, which are easily derived as

$$\frac{2^{\frac{\lambda_1}{f_1^*}} (1 - \frac{\lambda_1 \ln 2}{f_1^*})}{g_1} + \beta^* - \frac{1}{g_1} = 0 \quad (19)$$

$$\frac{2^{\frac{\lambda_2}{f_2^*}} (1 - \frac{\lambda_2 \ln 2}{f_2^*})}{g_2} + \beta^* - \frac{1}{g_2} = 0 \quad (20)$$

$$\frac{2^{\frac{\lambda_1}{f_3^*}} (1 - \frac{\lambda_1 \ln 2}{f_3^*})}{g_3} + \beta^* - \frac{1}{g_3} = 0 \quad (21)$$

$$\frac{2^{\frac{\lambda_2 - \lambda_1}{f_4^*}} (1 - \frac{(\lambda_2 - \lambda_1) \ln 2}{f_4^*})}{g_4} + \beta^* - \frac{1}{g_4} = 0 \quad (22)$$

$$\sum_{i=1}^4 f_i^* - 1 = 0 \quad (23)$$

where β^* is the Lagrange multiplier. Since (19)–(22) are transcendental equations, it is infeasible to obtain explicit solutions in general and numerical methods are instead employed to obtain the solution to problem **P2**.

C. Discussion and Insights

Firstly, we give a lemma that links each active mode (i.e., those for which $f_i^* > 0$) to the optimal solution to **P2**.

Lemma 3: Under the optimal solution to **P2**, we have for each active mode that

$$\frac{2^{R_i^*} (1 - R_i^* \ln 2)}{g_i} + \beta^* - \frac{1}{g_i} = 0. \quad (24)$$

Note that this result immediately follows from equations (19)–(22) and therefore the proof is omitted.

Based on Lemma 3, some observations can be made and are presented in the following proposition.

Proposition 1: The optimal transmit rates and optimal transmit powers in respect of channel gains for active modes (i.e., $f_i^*, f_j^* > 0$) are related as follows:

$$R_i^* > R_j^* \quad \text{and} \quad P_i^* < P_j^* \quad \Leftrightarrow \quad g_i > g_j \quad (25)$$

$$R_i^* = R_j^* \quad \text{and} \quad P_i^* = P_j^* \quad \Leftrightarrow \quad g_i = g_j \quad (26)$$

where $i, j = 1, 2, 3, 4, 5$. In other words, $R_i^* - R_j^*$ has the same sign as $g_i - g_j$ whereas $P_i^* - P_j^*$ has the opposite sign.

Proof: Let us multiply by g_i in (24), we then have the following equality for each active mode,

$$2^{R_i^*}(1 - R_i^* \ln 2) + \beta^* g_i - 1 = 0. \quad (27)$$

Note that R_i^* is an implicit function of g_i . Taking the derivatives on both sides in (27) with respect to g_i we obtain

$$-2^{R_i^*}(R_i^* \ln 2)^2 \frac{dR_i^*}{dg_i} + \beta^* = 0, \quad (28)$$

from which it follows that

$$\frac{dR_i^*}{dg_i} = \frac{\beta^*}{2^{R_i^*}(R_i^* \ln 2)^2} > 0. \quad (29)$$

The inequality comes from the fact that R_i^* for active modes and β^* are positive values. Hence R_i is a monotonically increasing function of g_i .

Recalling that $R_i^* = \log_2(1 + P_i^* g_i)$, (27) can also be written as

$$(P_i^* g_i + 1)(1 - \ln(1 + P_i^* g_i)) + \beta^* g_i - 1 = 0. \quad (30)$$

Taking derivatives with respect to g_i on both sides of (30) we arrive at

$$-\ln(1 + P_i^* g_i)(P_i^* + g_i \frac{dP_i^*}{dg_i}) + \beta^* = 0. \quad (31)$$

With some manipulations we can obtain (32)-(34) below.

$$\frac{dP_i^*}{dg_i} = \frac{\beta^* - P_i^* \ln(1 + P_i^* g_i)}{g_i \ln(1 + P_i^* g_i)} \quad (32)$$

$$= \frac{\ln(1 + P_i^* g_i) - P_i^* g_i}{g_i^2 \ln(1 + P_i^* g_i)} \quad (33)$$

$$< 0 \quad (34)$$

where (33) comes directly from (30) and (34) comes from the fact that $\ln(1 + x) < x$ if $x > 0$. Hence P_i^* is a strict decreasing function of g_i .

Considering both (29) and (34), Proposition 1 is proved. ■

It is interesting that Proposition 1 implies that the relative values of R_i^* and P_i^* depend only on the relative values of the corresponding channel gains, but not at all on the average arrival rates. The optimal time fraction for each mode, however, does relate to the corresponding arrival rate in the form $f_i^* = \frac{\lambda_i}{R_i^*}$.

Note also that Proposition 1, which relates the optimal power, rate and link gain in each mode, is useful for initializing the power and rate optimization routine so that the iterative procedure converges more quickly. For instance, if $g_1 > g_2$, we should initialize P_2 to exceed P_1 , and R_1 to exceed R_2 .

In addition, for the case that λ_1 and λ_2 are very small ($\lambda_i \ll 1$), we can use a Taylor series to approximate the exponential functions and obtain the closed form power allocation solution for each mode, with β obtained through a one-dimensional bisection search:

$$f_1^* = \lambda_1 \left(1 + \beta^* - \frac{1}{g_1} \right)^{\frac{1}{2}} \quad (35)$$

$$f_2^* = \lambda_2 \left(1 + \beta^* - \frac{1}{g_2} \right)^{\frac{1}{2}} \quad (36)$$

$$f_3^* = \lambda_1 \left(1 + \beta^* - \frac{1}{g_3} \right)^{\frac{1}{2}} \quad (37)$$

$$f_4^* = (\lambda_2 - \lambda_1) \left(1 + \beta^* - \frac{1}{g_4} \right)^{\frac{1}{2}} \quad (38)$$

$$f_4^* = 1 - f_1^* - f_2^* - f_3^*. \quad (39)$$

We should also emphasize that when $\lambda_1 > \lambda_2$, the last two terms in the cost function of **P2** change to

$$f_3 P_3 \left(\frac{\lambda_2}{f_3} \right) + f_5 P_5 \left(\frac{\lambda_1 - \lambda_2}{f_5} \right)$$

and the problem can be solved with the appropriate substitutions. Hence there is no loss in generality in the assumption that $\lambda_1 < \lambda_2$ that we used for the majority of this section.

III. MAXIMIZING ERGODIC ENERGY EFFICIENCY IN FADING CHANNELS

Unlike in the previous section, assume now that g_i , $i = 1, \dots, 5$, are random variables with known density functions $p(g_i)$. Assuming ergodicity in the random processes $g_i(t)$, where t represents time, minimization of average total transmit energy in the long run is formulated as **P3**:

$$\min_{f_i, R_i(g_i)} \sum_{i=1}^5 f_i \bar{P}_i \quad (40)$$

subject to

$$\lambda_1 \leq \min(f_1 \bar{R}_1, f_3 \bar{R}_3 + f_5 \bar{R}_5) \quad (41)$$

$$\lambda_2 \leq \min(f_2 \bar{R}_2, f_3 \bar{R}_3 + f_4 \bar{R}_4) \quad (42)$$

$$\sum_{i=1}^5 f_i \leq 1. \quad (43)$$

In the above

$$\bar{P}_i = E[P_i(R_i(g_i))] = \int_0^\infty P_i(R_i(g_i)) p(g_i) dg_i,$$

and

$$\bar{R}_i = E[R_i(g_i)] = \int_0^\infty R_i(g_i)p(g_i)dg_i,$$

where $\bar{P}_i$ and $\bar{R}_i$ are averaged over the channel gain distributions. We term problem **P3** an *ergodic energy efficiency maximization* problem. Note that the minimization is over $(f_i, R_i(g_i))$ once the functional form of $R_i(g_i)$ is found, we obtain $P_i(R_i(g_i))$ from (2) and hence $\bar{P}_i$, while $\bar{R}_i$ is obtained through averaging $R_i(g_i)$ over g_i .

In other words, solving problem **P3** yields a set of time fractions $\{f_i^*\}$ that minimizes an upper bound on the long-term average energy used, while guaranteeing long-term queue stability, assuming that the scheduler has knowledge of the instantaneous channel gains g_i , $i = 1, \dots, 5$, as well as the distribution of g_i . At the same time, we obtain a rate allocation $R_i^*(g_i)$ dependent on the instantaneous channel gains g_i .

It can be verified that Lemmas 1–2 still hold for this optimization problem and hence it can be translated into another equivalent optimization problem, as shown presently.

Again assuming without loss of generality that $\lambda_1 < \lambda_2$, **P3** reduces to **P4**:

$$\min_{f_i, R_i(g_i)} \sum_{i=1}^4 f_i \bar{P}_i \quad (44)$$

subject to

$$\lambda_1 = f_1 \bar{R}_1 = f_3 \bar{R}_3 \quad (45)$$

$$\lambda_2 = f_2 \bar{R}_2 \quad (46)$$

$$\lambda_2 - \lambda_1 = f_4 \bar{R}_4 \quad (47)$$

$$\sum_{i=1}^4 f_i \leq 1. \quad (48)$$

The Lagrangian function corresponding to **P4** is

$$F = \sum_{i=1}^4 f_i \bar{P}_i - \sum_{i=1}^4 \beta_i (f_i \bar{R}_i - \lambda_i) + \gamma \left(\sum_{i=1}^4 f_i - 1 \right) \quad (49)$$

where we used the notation $\lambda_3 = \lambda_1$ and $\lambda_4 = \lambda_2 - \lambda_1$ to denote virtual arrival rates for Mode 3 and Mode 4 respectively.

Fig. 2. Water filling diagram for each link.

Since **P4** is a convex optimization problem, its solution is given by the KKT conditions:

$$\bar{P}_i^* - \beta_i^* \bar{R}_i^* + \gamma^* = 0, \quad 1 \leq i \leq 4 \quad (50)$$

$$f_i^* \bar{R}_i^* - \lambda_i = 0, \quad 1 \leq i \leq 4 \quad (51)$$

$$f_i^* \frac{2^{R_i^*}}{g_i} \ln 2 - f_i^* \beta_i^* = 0, \quad 1 \leq i \leq 4 \quad (52)$$

$$\beta_i^*, \gamma^* \geq 0, \quad 1 \leq i \leq 4 \quad (53)$$

$$\sum_{i=1}^4 f_i^* = 1 \quad (54)$$

where the asterisks denote optimal values.

It can be found from (52) that $\frac{2^{R_i^*}}{g_i} = \beta_i^* \log_2 e$ and recall the power-rate equality in (2) we have

$$P_i^*(R_i^*(g_i)) = \left[\beta_i^* \log_2 e - \frac{1}{g_i} \right]^+ \quad (55)$$

Then by definition,

$$\bar{R}_i^* = \int_{\frac{1}{\beta_i^* \log_2 e}}^{\infty} \log_2(1 + P_i^*(R_i^*)g_i)p(g_i)dg_i \quad (56)$$

$$= \int_{\frac{1}{\beta_i^* \log_2 e}}^{\infty} \log_2(\beta_i^* g_i \log_2 e)p(g_i)dg_i \quad (57)$$

Therefore the power allocation solution over each link is of the form of water-filling and the illustrative diagram is shown in Fig. 2.

Note that $\bar{P}_i^*$ can also be found in terms of β_i^* and γ^* . The optimal f_i^* is given by (51). Finally, we obtain β_i^* and γ^* from (50) by performing a multidimensional bisection search method to make $\beta_i^* \bar{R}_i^* - \bar{P}_i^*$ equal (to γ^*) and positive for all i .

It is interesting to note that similar observations to Proposition 1 can be made for the ergodic energy optimization problem for Rayleigh fading channels. They are given in the following proposition. The detailed proof however is left in the appendix.

Proposition 2: Under the optimal solution to ergodic energy consumption optimization problem over Rayleigh fading channels, the relation of the optimal transmit power and rate of each mode with the associated average link gain can be given by,

$$\bar{P}_i^* < \bar{P}_j^* \quad \text{and} \quad \bar{R}_i^* > \bar{R}_j^* \quad \Leftrightarrow \quad \bar{g}_i > \bar{g}_j \quad (58)$$

$$\bar{P}_i^* = \bar{P}_j^* \quad \text{and} \quad \bar{R}_i^* = \bar{R}_j^* \quad \Leftrightarrow \quad \bar{g}_i = \bar{g}_j \quad (59)$$

where $i, j = 1, 2, 3, 4, 5$ if $f_i^*, f_j^* > 0$. In other words, $\bar{P}_i^*$ is a decreasing function of $\bar{g}_i$ whereas $\bar{R}_i^*$ is an increasing function of $\bar{g}_i$ in the ergodic case as well.

IV. SCHEDULING PROTOCOL: QUEUING AND ACTUAL ENERGY EFFICIENCY

We now consider scheduling strategies which make use of the optimal time-sharing fractions $\{f_i\}$ (and hence constant rates $\{R_i\}$ for **P1** and varying rate for **P3**) for each transmission mode when solving energy minimization problems **P1** and **P3** respectively. We then describe below an intuitive protocol called the energy-efficient random scheduling protocol (EERSP).

- 1) At the start of a packet interval of duration T , the relay randomly chooses a transmission mode with probability $P[\text{Mode } i] = f_i$.
- 2) If Mode 1 is selected, the relay will inform S_1 to transmit. If Mode 2 is selected, the relay will inform S_2 to transmit. The selected source will transmit if its data buffer is non-empty.
- 3) If Mode 3 is selected, the relay will transmit. If both queues at R are non-empty (i.e., $\min(Q_{r1}(\cdot), Q_{r2}(\cdot)) > 0$), it will broadcast network coded packets to both sources. If only $Q_{r1}(\cdot) > 0$ (or only $Q_{r2}(\cdot) > 0$), the relay will forward data to S_1 (or S_2). If both queues at R are empty, it will remain silent.
- 4) If Mode 4 is selected, the relay will forward packets to S_1 if $Q_{r1}(\cdot) > 0$. If Mode 5 is selected, the relay will forward packets to S_2 if $Q_{r2}(\cdot) > 0$.

A. Queue Analysis for **P1**

We now analyze the queuing performance of EERSP. The data arrival processes at both S_1 and S_2 are assumed to be Poisson. For brevity, we shall only focus on the queue length $Q_1(t)$ and $Q_{r2}(t)$. The analysis for $Q_2(t)$ and $Q_{r1}(t)$ is very similar to that for $Q_1(t)$ and $Q_{r2}(t)$ and is omitted for brevity.

Here we use a two-dimensional Markov chain to model the backlog states of $(Q_1(t), Q_{r2}(t))$ and define $q_{(m,k),(i,j)}$ as the one-step transition probability of the event that $Q_{r2}(t+1) = j$ and $Q_1(t+1) = i$ given that $Q_{r2}(t) = k$ and $Q_1(t) = m$. There are four classes of queue transitions arising from the five transmission modes:

Class I: S_1 is selected for transmission in Mode 1;

Class II: R is selected for transmission in Mode 3;

Class III: Mode 2 or Mode 4 is selected;

Class IV: R is selected for transmission in Mode 5.

Without loss of generality, assume that one time slot of duration T corresponds to one channel use, and that capacity is measured in units of packets. Hence, for Mode 1 transmission, where a rate R_1^* is supported, we assume that a maximum of R_1^* packets can be transmitted from S_1 to R . In general, in Mode i , a maximum of R_i^* packets can be transmitted. The queue analysis below follows naturally from this view.

For Class I up to R_1^* , packets may be received reliably at R from S_1 , the conditional one-step transition probability is

$$q_{(m,k),(i,j)} = \begin{cases} a_i, & m = 0, j = k \\ a_i, & 0 < m < R_1^*, j = k + m \\ a_{i-m+R_1}, & m \geq R_1^*, j = k + R_1^* \end{cases} \quad (60)$$

where

$$a_j = \frac{(\lambda_1 T)^j}{j!} \exp(-\lambda_1 T) \quad (61)$$

is the probability that j packets arrive at S_1 within the current slot. For the the case where $Q_1(t) = 0$, no packets are queued for transmission by S_1 , therefore $Q_{r2}(t+1) = Q_{r2}(t)$. For $Q_1(t+1)$ to be equal to i , there must have been i arrivals at S_1 in the duration T of the $(t+1)$ -st slot.

For the case where $0 < Q_1(t) < R_1^*$, all queued packets at S_1 will be transmitted during slot $t+1$ and hence $Q_{r2}(t+1) = Q_{r2}(t) + Q_1(t)$. Therefore, $Q_1(t+1)$ is determined by the number of packets arrived during slot $t+1$.

For the case that $Q_1(t) > R_1^*$, we have $Q_{r2}(t+1) = Q_{r2}(t) + R_1^*$ since S_1 can transmit at most R_1^* packets during one slot. $Q_1(t+1)$ is thus determined both by the number of residual buffed packets $Q_1(t) - R_1^*$ and the number of new packet arrivals, i.e, $Q_1(t+1) = Q_1(t) - R_1^* + i$ provided that there are i arrivals during slot $t+1$. It should be noted that there are no other possible transitions.

Fig. 3. Two-dimensional Markov chain corresponding to EERSP protocol

Under Class II, R will transmit network coded data to S_2 in Mode 3. In this scenario, queue length increment at S_1 is determined by the number of arrived packets at S_1 within this slot. For queueing at R for S_2 , there will be two cases after transmission. If $Q_{r2}(t)$ is less than R_3^* , it will be emptied at slot $t + 1$. Otherwise, there will be still $Q_{r2}(t) - R_3^*$ packets buffered at R for S_2 . The conditional transition probability thus can be given as by

$$q_{(m,k),(i,j)} = \begin{cases} a_{i-m}, & j = 0, k \leq R_3^* \\ a_{i-m}, & j = k - R_3^*, k > R_3^* \end{cases} \quad (62)$$

Under Class III, Q_{r2} remains the same in the next slot. Only the external arrival at S_1 will change the state of $Q_1(t)$. The conditional transition probability thus is

$$q_{(m,k),(i,j)} = a_{i-m}, \quad j = k \quad (63)$$

The analysis for Class IV is similar to that for Class II and is omitted for brevity.

Combining all these modes and current queue state, the state space and corresponding transition probability for $Q_1(t)$ and $Q_{r2}(t)$ of the EERSP protocol are given below and is shown in Fig. 3.

To simplify the analysis, the one-step transition probability matrix of the two-dimensional Markov chain can be written as that of a one-dimensional Markov chain, i.e., $\mathbf{P} = \{q_{mn+k,in+j}\}$ where n is a large positive number and $q_{(m,k),(i,j)}$ is represented by the element of $\mathbf{P}_{mn+k,in+j}$. The stationary distribution thus is

$$\pi = \mathbf{1} \cdot (\mathbf{I} - \mathbf{P} + \mathbf{\Theta})^{-1}. \quad (64)$$

The average queue length at S_1 and that at R for S_2 then are

$$\overline{Q_1} = \sum_{i=0}^{\infty} \sum_{j=0}^n i \pi_{in+j} \quad (65)$$

$$\overline{Q_{r2}} = \sum_{i=0}^{\infty} \sum_{j=0}^n j \pi_{in+j} \quad (66)$$

B. Queue and Delay Analysis for **P3**

The analysis of queueing for the fading channel problem is similar to the analysis of the static channel problem in the above subsection. The four classes of state transitions still apply, but the rates supported in each mode are no longer constant. They are instead random variables due to (55), which makes R_i^* a function of g_i , a random variable. Therefore, we define c_n as the probability that S_1 is only able to transmit n packets in one slot if it is selected for transmission, while r_n and q_n are the probability that R can transmit n packets in one slot if it is selected for transmission in Mode 3 and Mode 5 respectively.

For Class I, packets may be received reliably at R from S_1 , the conditional one-step transition probability then is

$$q_{(m,k),(i,j)} = \begin{cases} a_i, & m = 0, j = k \\ a_i \cdot \sum_{n=m}^{\infty} c_n, & 0 < m, j = k + m \\ a_{i-m+n} c_n, & 0 \leq n < m, j = k + n \end{cases} \quad (67)$$

Where a_i is as defined in the previous subsection. The first term on the right hand side of (67) represents the case that $Q_1(t)$ is zero. As no packets are queued at S_1 for transmission, we have $Q_{r2}(t+1) = Q_{r2}(t)$ and $Q_1(t+1)$ is determined by the number of packets arrival in the duration T of the $t+1$ st slot. The second term accounts for the case that the instantaneous transmit rate $R_1^*(t)$ of S_1 is higher than $Q_1(t)$ and hence $Q_{r2}(t+1) = Q_{r2}(t) + Q_1(t)$. The probability that $R_1^*(t) \geq Q_1(t)$ is given by $\sum_{i=Q_1(t)}^{\infty} c_i$. In this case, $Q_1(t+1)$ is also determined by the number of new arrivals during slot $t+1$ since packets buffered previously are totally delivered to R . For the third term where $R_1^*(t) < Q_1(t)$, we have $Q_2(t+1) = Q_2(t) + R_1^*(t)$ since only as most $R_1^*(t)$ packets can be transmitted during one slot. $Q_1(t+1)$ is hence given by the sum of the number of residual buffered packets and the number of new arrivals, i.e., $Q_1(t+1) = Q_1(t) - R_1^*(t) + i$ given there are i arrivals during slot $t+1$.

For Class II, R will transmit network coded data to S_2 in Mode 3. The conditional transition probability is given as follows.

$$q_{(m,k),(i,j)} = \begin{cases} a_{i-m} \sum_{n=k}^{\infty} r_n, & j = 0 \\ a_{i-m} r_n, & j = k - n, 0 \leq n < k \end{cases} \quad (68)$$

Where queue length increment at S_1 is determined by the number of arrived packets at S_1 within this slot. For queueing at R for S_2 , $Q_{r2}(t+1)$ is determined by current buffering length $Q_{r2}(t)$ and the instantaneous broadcasting rate of R , i.e., $R_3^*(t)$. If $Q_{r2}(t) < R_3^*(t)$, it will be emptied at slot $t + 1$. Otherwise, there will be still $Q_{r2}(t) - R_3^*(t)$ packets buffered at R for S_2 .

Similarly, we can get the one-step transition probability for Class III and Class IV. Combining them together, the one-step transition probability of the EERSP protocol with ergodic energy optimization can be given as follows.

$$q_{(m,k),(i,j)} = \begin{cases} a_i, & m = k = j = 0 \\ (1 - f_1 + f_1 c_0) a_{i-m}, & m > 0, k = j = 0 \\ (f_3 r_n + f_5 q_n) a_{i-m}, & j = k - n, k > 0, 0 \leq n < k \\ a_{i-m} (f_3 \sum_{n=m}^{\infty} r_n + f_5 \sum_{n=m}^{\infty} q_n), & j = 0, k > 0 \\ (f_2 + f_4 + f_1 + f_3 r_0 + f_5 q_0) a_i, & j = k > 0, m = 0 \\ (f_2 + f_4 + f_1 c_0 + f_3 r_0 + f_5 q_0) a_{i-m}, & j = k > 0, m > 0 \\ f_1 a_{i-m+n} c_n, & m > 0, j = k + n, 0 \leq n \leq m - 1 \\ f_1 a_i \cdot \sum_{n=m}^{\infty} c_n, & 0 < m, j = k + m \\ 0, & \text{else} \end{cases} \quad (69)$$

In a similar manner, average queue length of S_1 and that of R for S_2 can be characterized by using (64)-(66).

C. Practical Energy Consumption with Positive ϵ

To ensure reasonable running times and memory requirements in simulation, we design for average arrival rates that are slightly larger than the actual rates, i.e., $\lambda_i \rightarrow (1 + \epsilon)\lambda_i$ ($i = 1, 2$), where ϵ is a small positive value. In this case it should be noted that the actual consumed energy might be lower than the designed energy consumption with positive ϵ since there might be idle slots of each active mode in implementation. Therefore, it is interesting to investigate actual energy consumption in the regime of positive ϵ and this is what will be done in this section. Note that here we only focus on the constant link gain scenario. The practical energy consumption under the scenario of fading channel can be derived in a similar manner and is hence omitted.

Let f_i^* be the optimal time fraction of each mode for *virtual* arrival rate pair $(\lambda_1(1 + \epsilon), \lambda_2(1 + \epsilon))$. Let P_i^* be the optimal power level and R_i^* the optimal transmit rate of Mode i for *virtual* arrival rate pair. Let π_{ij}^1 be the stationary distribution for queue pair $(Q_1(t), Q_{r2}(t))$ and π_{ij}^2 be the stationary distribution of queue pair $(Q_2(t), Q_{r1}(t))$ respectively for *actual* arrival rate pair. Considering the two exclusive scenarios that $Q_i(t) < R_i^*$ and that $Q_i(t) > R_i^*$ together, we can derive the actual energy consumption for each active mode respectively.

For Modes 1 and 2, the actual energy consumed can be given by,

$$\bar{E}'_i = \sum_{k=R_i^*}^{\infty} \sum_{j=0}^{\infty} \pi_{kj}^i P_i^* + \sum_{k=0}^{R_i^*-1} \sum_{j=0}^{\infty} \left(\pi_{kj}^i \cdot \frac{2^k - 1}{g_i} \right) \quad i = 1, 2 \quad (70)$$

where the first term accounts for the case that current queue length is higher than transmit rate of this mode whereas the second term accounts for $Q_i(t) < R_i^*$.

Similarly, for Modes 4 or 5 whichever is active ($f_i^* > 0$), the actual energy consumed is given by,

$$\bar{E}'_i = \sum_{k=R_i^*}^{\infty} \sum_{j=0}^{\infty} \pi_{jk}^{6-i} P_i^* + \sum_{k=0}^{R_i^*-1} \sum_{j=0}^{\infty} \left(\pi_{jk}^{6-i} \cdot \frac{2^k - 1}{g_i} \right) \quad i = 4(5) \quad (71)$$

For Mode 3, the actual energy consumed is given by,

$$\bar{E}'_i = \sum_{\max(l,j) > R_i^*} \pi_{ml}^1 \pi_{kj}^2 P_i^* + \sum_{\max(l,j) \leq R_i^*} \left(\pi_{ml}^1 \pi_{kj}^i \cdot \frac{2^{\max(l,j)} - 1}{g_i} \right) \quad i = 3 \quad (72)$$

Combining them together with optimal time fraction assigned for each mode, actual energy consumed per slot for this entire network, $\bar{E}_{act}$, is given by

$$\bar{E}_{act} = \sum_{i=1}^5 f_i^* \bar{E}'_i. \quad (73)$$

We shall compare this actual energy consumption with the simulation result in the following section.

V. SIMULATION

We now present simulations to verify our findings and explore tradeoffs. To ensure reasonable running times and memory requirements, we design for average arrival rates that are slightly larger than the actual rates, i.e., $\lambda_i \rightarrow (1 + \epsilon)\lambda_i$ ($i = 1, 2$), where ϵ is a small positive value. Noise at each node is assumed to be Gaussian with zero mean and unit variance and Rayleigh fading models are used for each link.

In Fig. 4, the data arrival rate at S_2 is $\lambda_2 = 1$. An iterative sequential quadratic program (SQP) is used to solve **P1** directly, and **P2** is solved through a numerical solution of the KKT equations. It can be observed that the solution to **P1** and the solution to **P2** matches for different channel gain realizations and varying λ_1 . The equivalence of problems **P1** and **P2** is therefore verified. In a similar manner, we have also numerically verified that P3 and P4 are equivalent, but omit the results in the interest of conciseness.

In Fig. 5, the energy efficiency of short term digital network coding and the conventional scheme (without network coding) are compared for some specified channel realizations. The energy required for

supporting data arrival rate with conventional transmission is obtained by solving the problem below.

$$\min_{f_i} \quad \left(f_1 P_1\left(\frac{\lambda_1}{f_1}\right) + f_2 P_2\left(\frac{\lambda_2}{f_2}\right) + f_4 P_4\left(\frac{\lambda_2}{f_4}\right) + f_5 P_5\left(\frac{\lambda_1}{f_5}\right) \right) \quad (74)$$

$$s.t. \quad f_i \geq 0 \quad (75)$$

$$\sum_{i=1}^5 f_i = 1 \quad (76)$$

$$f_3 = 0 \quad (77)$$

It can be observed that energy efficiency is greatly improved by employing network coding. For instance, in the case of unit channel gains, energy is reduced from 31 units to 15 units, at $\lambda_1 = 1.5$.

In Fig. 6, the energy consumption of the ergodic digital network coding solution **P3**, static-channel digital network coding solution **P1** and the ergodic conventional non-NC solution are compared, where the conventional non-NC solution is obtained by solving **P3** with $f_3 = 0$. The energy consumption of the static-channel DNC solution was obtained by averaging over 200 channel realizations.

It can be observed that energy efficiency is greatly improved by employing network coding. For instance, in the case of unit average channel gain, energy usage is reduced from over 50 units to less than 30 units, at $\lambda_1 = 1.5$. It is also observed that with network coding, optimizing over long term varying link gain can save even more energy, since it mitigates the adverse effect of deep fading scenario compared with short term DNC solution. Under the scenario of unit average channel gains, total energy consumed is reduced from over 70 units to less than 30 units, at $\lambda_1 = 1.5$.

We study the actual energy consumption by implementing EERSP protocol for the static-channel DNC in Fig. 7. In simulation, we ran 10^6 slots and channels of each link are kept static throughout the simulation. It can be seen that the analytical result of actual energy usage matches well with the simulation result. As expected, the actual energy usage is less than the upper bound determined by the optimal energy minimization solution because the backoff parameter ϵ was non-zero.

In the following, we show the tradeoff between energy efficiency and queue length. The data arrival process at each source node is assumed to be Poisson. We also set $\lambda_1 = 0.5$ frame/slot and $\lambda_2 = 1$ frame/slot and each slot spans 1ms. The bandwidth is set to be 1kHz. All link gains are assumed to be unity and Gaussian noise at each node is assumed to have zero mean and unit variance.

In Fig. 8 and Fig. 9, average queue length of the EERSP protocol for **P1** and for **P3** are shown respectively. It can be seen that the analytical result and simulation for queue length at both S_1 and at

Fig. 4. Optimal total energy consumption for some specified channel realizations for constant channel gains. λ_2 is set to be constant

R for S_2 match with each other perfectly. It is also observed that with increasing ϵ , the queue length at S_1 decreases quickly due to higher transmission rate for each mode. However, increasing ϵ results in an increased probability of idle slots as we are over-provisioning the system, and therefore lower bandwidth efficiency. The factor ϵ thus controls the trade-off between bandwidth efficiency and buffering delay.

VI. CONCLUSION

In this work, the minimal-energy allocation of resources to the five transmission modes in a two-way relay network with digital network coding at the relay and stochastic packet arrivals at the two source nodes was obtained. Both static and fading channels were accounted for, in the static-channel and ergodic energy minimization problems respectively. The proposed solutions ensure stability of all four queues in the network for arbitrary average packet arrival rates. The ergodic energy minimization solution has a water-filling structure and lower energy usage compared to re-designing the system to match the instantaneous channel gains using the static-channel energy minimization solution in a fading channel. In addition, a practical scheduling protocol was introduced to implement the proposed resource allocation solutions, and an exact queuing analysis of the protocol was obtained. As two-way relay networks appear in many applications including cellular networks and satellite systems, the work presented here is an

APPENDIX A

PROOF FOR PROPOSITION 2

In this appendix, we give the proof for Proposition 2. Firstly, let us recall that the probability density function (pdf) of link gain over a Rayleigh fading channel is given by

$$p(g_i) = \frac{1}{\bar{g}_i} \exp\left(-\frac{g_i}{\bar{g}_i}\right). \quad (78)$$

Hence, substituting (78) into (57), we can derive $\bar{R}_i^*$ as follows.

$$\bar{R}_i^* = \int_{\frac{1}{\beta_i^* \log_2 e}}^{\infty} \log_2(\beta_i^* g_i \log_2 e) \frac{1}{\bar{g}_i} \exp\left(-\frac{g_i}{\bar{g}_i}\right) dg_i \quad (79)$$

$$= -\log_2(c_i g_i) \exp\left(-\frac{g_i}{\bar{g}_i}\right) \Big|_{c_i^*}^{\infty} + \int_{\frac{1}{c_i^*}}^{\infty} \frac{1}{g_i \ln 2} \exp\left(-\frac{g_i}{\bar{g}_i}\right) dg_i \quad (80)$$

$$= \int_{\frac{1}{c_i^*}}^{\infty} \frac{1}{g_i \ln 2} \exp\left(-\frac{g_i}{\bar{g}_i}\right) dg_i \quad (81)$$

$$= \int_1^{\infty} \frac{1}{g_i \ln 2} \exp\left(-\frac{g_i}{c_i^* \bar{g}_i}\right) dg_i \quad (82)$$

Where $c_i^* = \beta_i^* \log_2 e$ for short. In the same manner, $\bar{P}_i^*$ is given by,

$$\bar{P}_i^* = \int_{\frac{1}{c_i^*}}^{\infty} \frac{1}{g_i^2} \exp\left(-\frac{g_i}{\bar{g}_i}\right) dg_i \quad (83)$$

$$= \int_1^{\infty} \frac{c_i^*}{g_i^2} \exp\left(-\frac{g_i}{c_i^* \bar{g}_i}\right) dg_i. \quad (84)$$

Substituting (82) and (84) into (50), we obtain the following lemma.

Lemma 4: Under the optimal energy solution **P4** over Rayleigh fading channels, optimal power level and optimal rate of each active mode can be linked by

$$\int_1^{\infty} \left(\frac{c_i^*}{g_i^2} - \frac{c_i^*}{g_i}\right) \exp\left(-\frac{g_i}{c_i^* \bar{g}_i}\right) dg_i + \gamma^* = 0. \quad (85)$$

Note that c_i^* is an implicit function of $\bar{g}_i$. Take derivatives with respect to $\bar{g}_i$ on both sides of (85), we obtain

$$\frac{dc_i^*}{d\bar{g}_i} \frac{\int_1^{\infty} \left(\frac{1}{g_i^2} - \frac{1}{g_i}\right) \exp\left(-\frac{g_i}{c_i^* \bar{g}_i}\right) dg_i}{c_i^*} + \frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} \frac{\int_1^{\infty} \left(\frac{1}{g_i} - 1\right) \exp\left(-\frac{g_i}{c_i^* \bar{g}_i}\right) dg_i}{c_i^* \bar{g}_i^2} = 0. \quad (86)$$

Since $\frac{1}{g_i^2} - \frac{1}{g_i} < 0$ and $\frac{1}{g_i} - 1 < 0$ hold if $g_i > 1$, it can be deduced that $\frac{dc_i^*}{d\bar{g}_i}$ and $\frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i}$ are with different signs, i.e., $\frac{dc_i^*}{d\bar{g}_i} \frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} < 0$.

Hence there are only two feasible scenarios: 1) $\frac{dc_i^*}{d\bar{g}_i} > 0$ and $\frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} < 0$; 2) $\frac{dc_i^*}{d\bar{g}_i} < 0$ and $\frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} > 0$. However, it can be immediately deduced that, if $\frac{dc_i^*}{d\bar{g}_i} > 0$, $\frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} = c_i^* + \bar{g}_i \frac{dc_i^*}{d\bar{g}_i} > 0$ given $c_i^*, \bar{g}_i > 0$. A

contradiction occurs for scenario 1) and it cannot be feasible. Therefore the latter scenario is uniquely feasible, i.e., $\frac{dc_i^*}{d\bar{g}_i} < 0$ and $\frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} > 0$.

Based on the above analysis, we seek to find the relation of $\bar{P}_i^*$ and $\bar{R}_i^*$ with $\bar{g}_i$ by deriving the first-order derivative of $\bar{P}_i^*$ and $\bar{R}_i^*$ with respect to $\bar{g}_i$ for each active mode.

From (82), the derivative of R_i^* with respect to $\bar{g}_i$ can be given by,

$$\frac{d\bar{R}_i^*}{d\bar{g}_i} = \frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} \cdot \frac{\int_1^\infty \frac{1}{\ln 2} \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i}{(c_i^* \bar{g}_i)^2} > 0 \quad (87)$$

where (87) comes from the conclusion that $\frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} > 0$. Therefore, $\bar{R}_i^*$ is an increasing function of $\bar{g}_i$ for each active mode in the ergodic case as well.

In a similar way, the derivative of P_i^* in (84) with respect to $\bar{g}_i$ is derived as follows.

$$\frac{d\bar{P}_i^*}{d\bar{g}_i} = \frac{dc_i^*}{d\bar{g}_i} \frac{P_i^*}{c_i^*} + \frac{d(\bar{g}_i c_i^*)}{d\bar{g}_i} \cdot \frac{\int_1^\infty \frac{1}{g_i} \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i}{(c_i^* \bar{g}_i)^2} \quad (88)$$

$$= \frac{dc_i^*}{d\bar{g}_i} \left(\frac{\int_1^\infty \frac{1}{g_i^2} \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i \int_1^\infty (1 - \frac{1}{g_i}) \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i}{\int_1^\infty (1 - \frac{1}{g_i}) \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i} - \frac{\int_1^\infty \frac{1}{g_i} \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i \int_1^\infty (\frac{1}{g_i} - \frac{1}{g_i^2}) \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i}{\int_1^\infty (1 - \frac{1}{g_i}) \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i} \right) \quad (89)$$

$$= \frac{dc_i^*}{d\bar{g}_i} \frac{\int_1^\infty \frac{1}{g_i^2} \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i \int_1^\infty \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i - (\int_1^\infty \frac{1}{g_i} \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i)^2}{\int_1^\infty (1 - \frac{1}{g_i}) \exp(-\frac{g_i}{c_i^* \bar{g}_i}) dg_i} \quad (90)$$

$$< 0 \quad (91)$$

where (89) can be obtained by substituting the equality of (86) into (88) and (91) comes from Cauchy-Schwarz inequality and the fact that $\frac{dc_i^*}{d\bar{g}_i} < 0$.

Hence $\bar{P}_i^*$ is an increasing function of $\bar{g}_i$ for each active mode in the ergodic case as well. Proposition 2 then is proved.
